Reinforcement Learning HSE, autumn - winter 2022 Lecture 7: Multi-armed Bandits

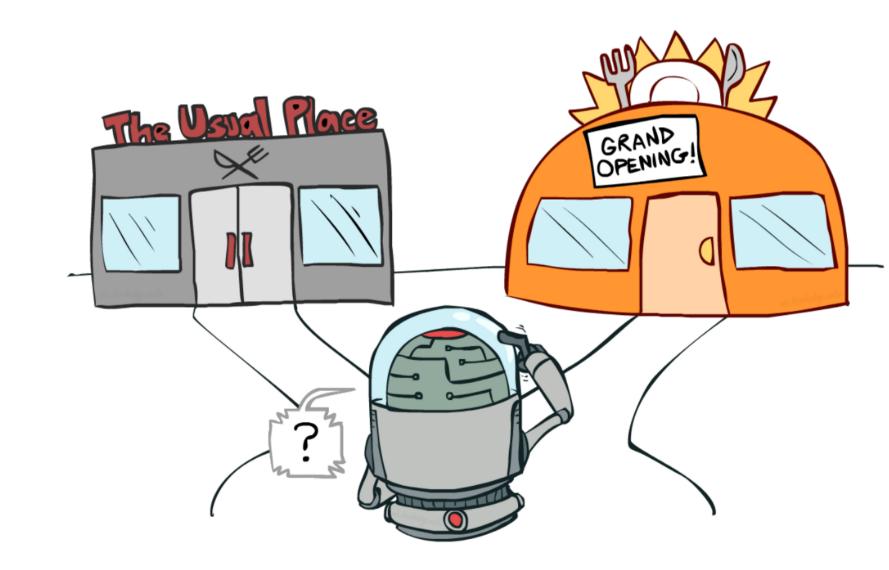

Sergei Laktionov slaktionov@hse.ru LinkedIn

Background

- 1. Practical RL course by YSDA, week 5
- 2. Sutton & Barto, Chapter 2
- 3. <u>DeepMind course</u>, Lecture 2
- 4. <u>David Silver Course</u>, Lecture 9

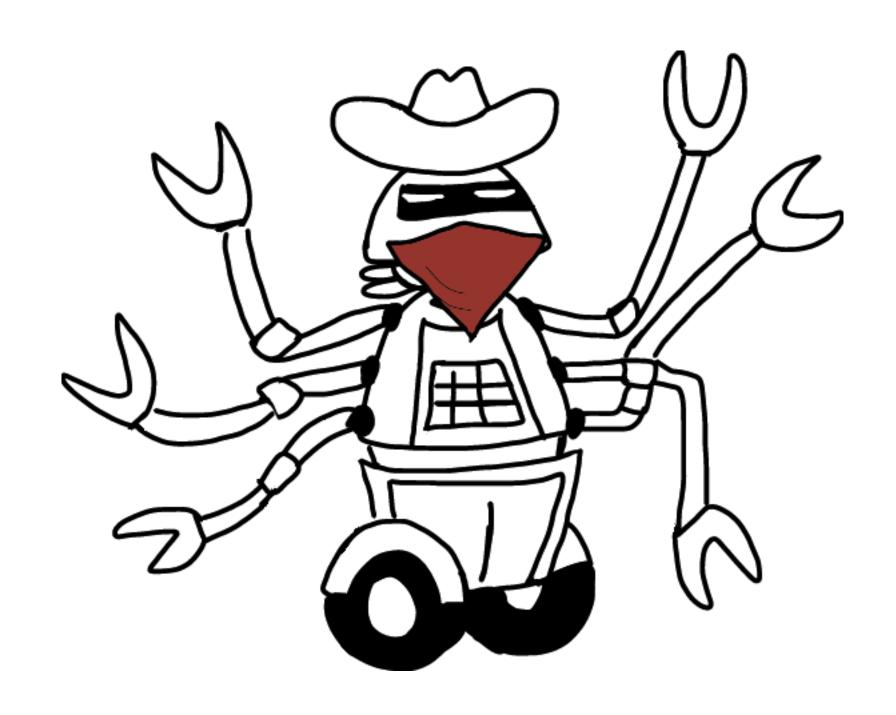

Exploration vs Exploitation Dilemma

- Online decision-making involves a fundamental choice:
 - Exploitation Make the best decision given current information
 - Exploration Gather more information
- The best long-term strategy may involve short-term sacrifices
- Gather enough information to make the best overall decisions

Source

Assume that the episode ends after the first step so we have only one state in the environment. An agent is facing repeatedly with a choice among k different actions.

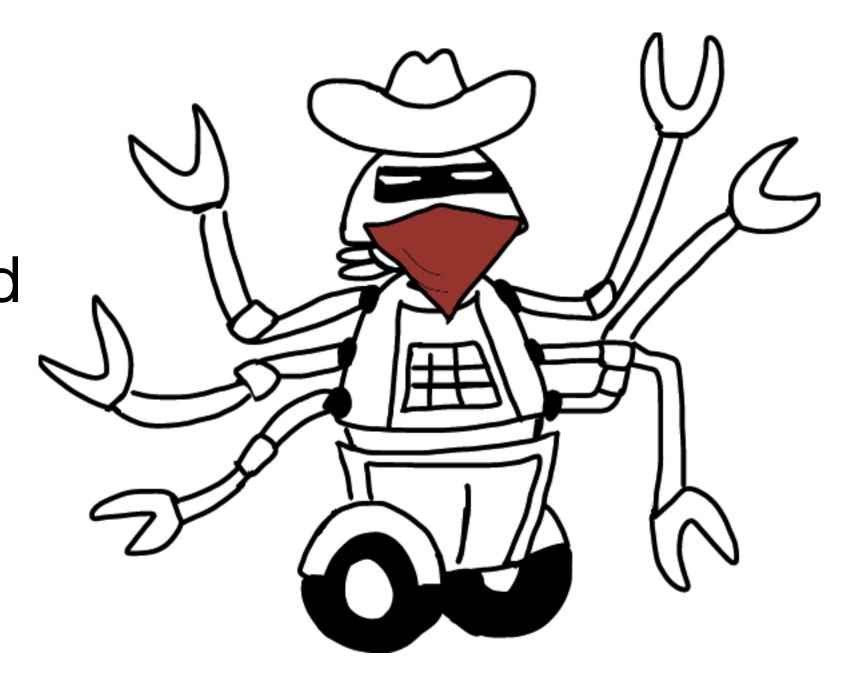

Assume that the episode ends after the first step so we have only one state in the environment. An agent is facing repeatedly with a choice among k different actions.

A multi-armed bandit is a tuple $\langle \mathcal{R}, \mathcal{A} \rangle$ s.t.:

- $\{\mathcal{R}_a \mid a \in \mathcal{A}\}$ set of reward distributions;
- On each step t an agent chooses A_t and get reward $R_t \sim \mathcal{R}_{A_t}$

The agent's goal is to maximise $\mathbb{E}_{p(r|a)}[\sum_{t=1}^{r}R_t]$ by choosing an action on each step.

Exploration: find the best action which maximises expected reward

Action value function: $Q(a) = \mathbb{E}[R_t | A_t = a]$

Optimal value: $V^* = \max_a Q(a)$

Regret: $\mathbb{E}_{\pi}[V^* - Q(a)] \geq 0$

Exploration: find the best action which maximises expected reward

Action value function:
$$Q(a) = \mathbb{E}[R_t | A_t = a]$$

Optimal value:
$$V^* = \max_a Q(a)$$

Regret:
$$\mathbb{E}_{\pi}[V^* - Q(a)] \geq 0$$

Total Regret:
$$\mathbb{E}_{\pi} \sum_{t=1}^{T} \left[V^* - Q(a_t) \right] \rightarrow \min_{\pi}$$

Note: as we don't have states policy π is just a rule of making decision on each step.

Exploration: find the best action which maximises expected reward

Action value function: $Q(a) = \mathbb{E}[R_t | A_t = a]$

Optimal value: $V^* = \max_a Q(a)$

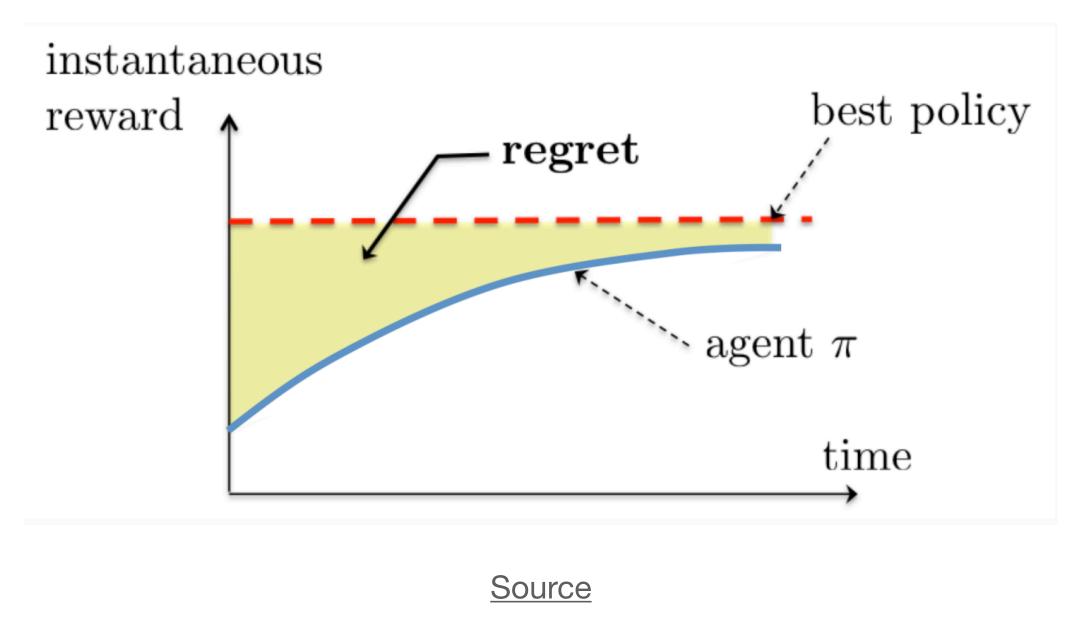

Regret: $\mathbb{E}_{\pi}[V^* - Q(a)] \ge 0$

 $\textbf{Total Regret:} \ \mathbb{E}_{\pi} \sum_{t=1}^{T} \left[V^* - Q(a_t) \right] \rightarrow \min_{\pi} \iff \mathbb{E}_{p(r|a)} [\sum_{t=1}^{T} R_t] \rightarrow \max_{\pi}$

Note: as we don't have states policy π is just a rule of making decision on each step.

Regret Minimisation

$$\textbf{Total Regret:} \ \mathbb{E}_{\pi} \sum_{t=1}^{T} \left[V^* - Q(a_t) \right] \rightarrow \min_{\pi} \iff \mathbb{E}_{p(r|a)} \left[\sum_{t=1}^{T} R_t \right] \rightarrow \max_{\pi}$$

Action Values

$$Q_{t}(a) = \frac{\sum_{n=1}^{t} \mathbb{I}(A_{n} = a)r_{n}}{\sum_{n=1}^{t} \mathbb{I}(A_{n} = a)} = \frac{\sum_{n=1}^{t} \mathbb{I}(A_{n} = a)r_{n}}{N_{t}(a)} \iff$$

Action Values

$$Q_{t}(a) = \frac{\sum_{n=1}^{t} \mathbb{I}(A_{n} = a)r_{n}}{\sum_{n=1}^{t} \mathbb{I}(A_{n} = a)} = \frac{\sum_{n=1}^{t} \mathbb{I}(A_{n} = a)r_{n}}{N_{t}(a)} \iff Q_{t}(A_{t}) = Q_{t-1}(A_{t}) + \alpha_{t}[r_{t} - Q_{t-1}(A_{t})]$$

$$\alpha_{t} = \frac{1}{N_{t}}, N_{t}(A_{t}) = N_{t-1}(A_{t}) + 1$$

ε -greedy Policy

$$\pi_{t}(a) = \begin{cases} (1 - \varepsilon) + \frac{\varepsilon}{|\mathcal{A}|}, & \text{if } Q_{t}(a) = \max_{a'} Q_{t}(a') \\ \frac{\varepsilon}{|\mathcal{A}|}, & \text{otherwise} \end{cases}$$

- Greedy policy can stuck in a suboptimal action forever
- ε -greedy continues to explore

ε -greedy Policy

$$\pi_{t}(a) = \begin{cases} (1 - \varepsilon) + \frac{\varepsilon}{|\mathcal{A}|}, & \text{if } Q_{t}(a) = \max_{a'} Q_{t}(a') \\ \frac{\varepsilon}{|\mathcal{A}|}, & \text{otherwise} \end{cases}$$

- Greedy policy can stuck on a suboptimal action forever
- ε -greedy continues to explore

 ε -greedy policy has linear regret

Gradient Policy

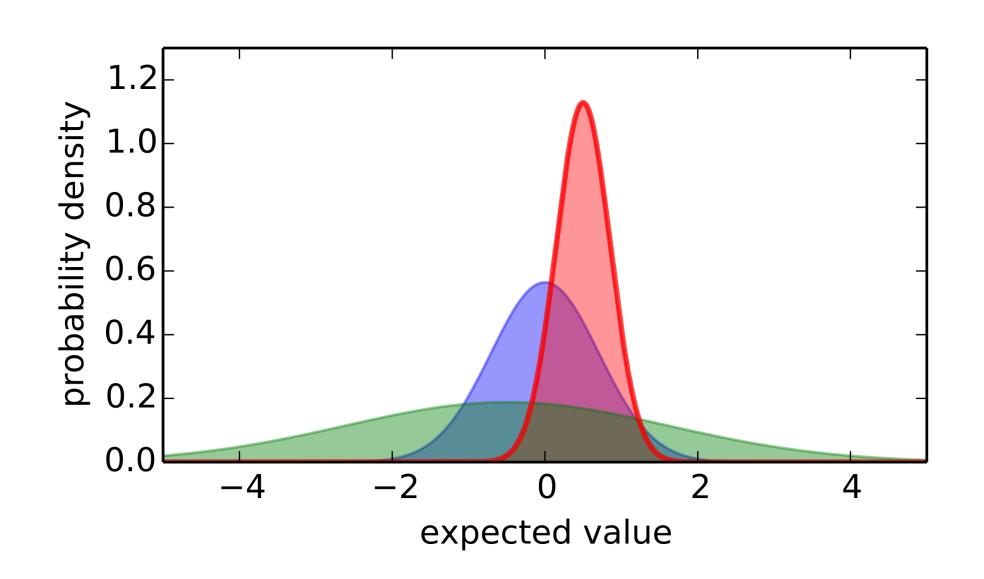

We can learn softmax policy using REINFORCE via gradient ascent, but there is no still guarantees for convergence to a global optimum.

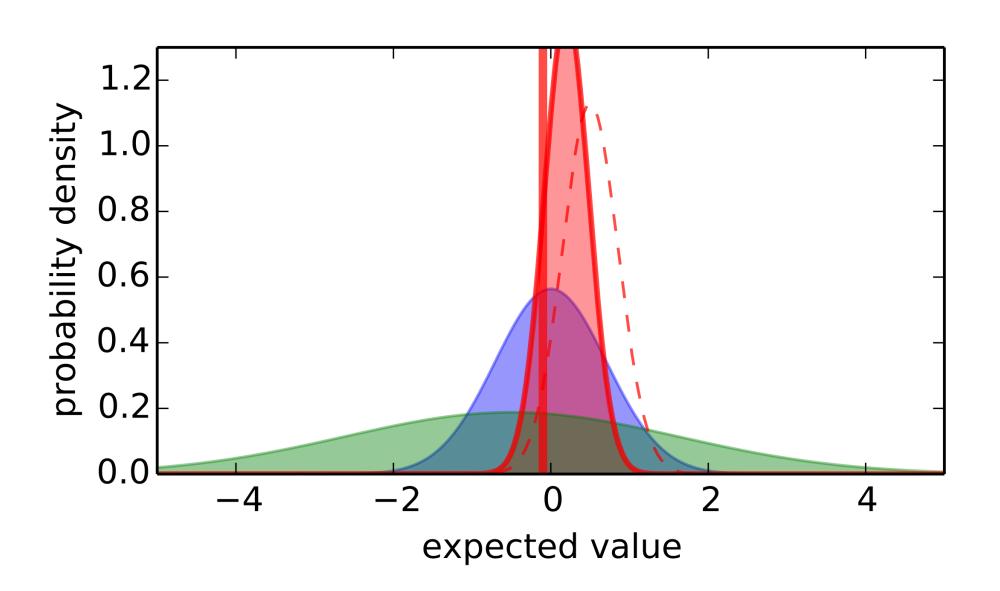

Regret Lower Bound

Theorem:

$$\mathbb{E}_{\pi} \sum_{t=1}^{T} \left[V^* - Q(a_t) \right] \ge \log T \sum_{a \mid V^* > Q(a)} \frac{V^* - Q(a)}{KL(\mathcal{R}_a \mid |\mathcal{R}_{a^*})}$$

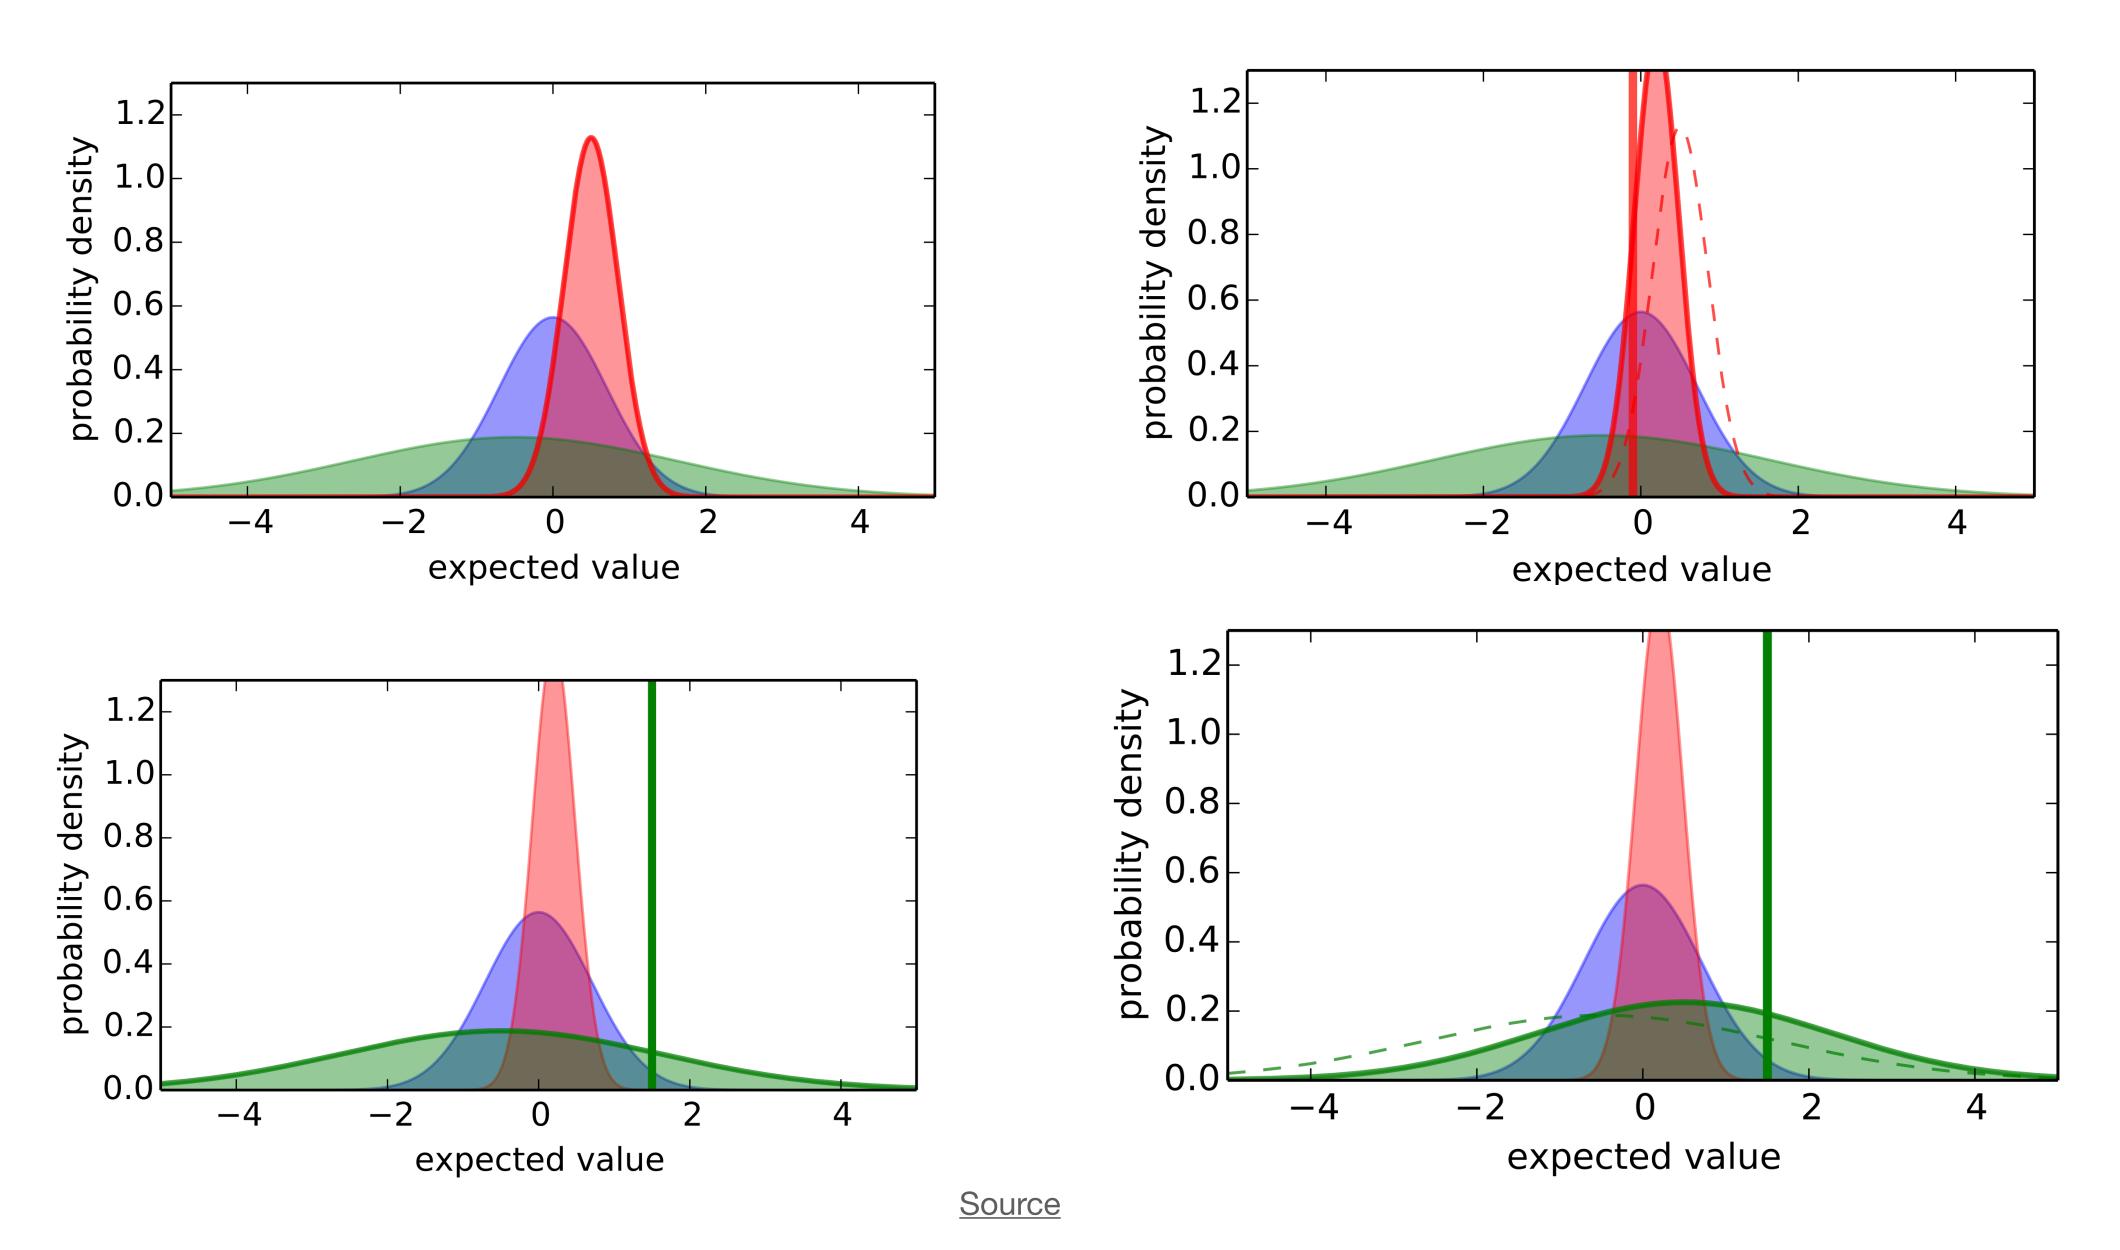

Optimism in the Face of Uncertainty

- Which action should we pick?
- The more uncertain we are about an action-value the more important it is to explore that action
- It could turn out to be the best action

Optimism in the Face of Uncertainty

Upper Confidence Bound

- Estimate an upper confidence $U_t(a)$ for each action value, such that $Q(a) \leq Q_t(a) + U_t(a)$ with high probability.
- This depends on the number of times N(a) has been selected
 - Small $N(a) \Rightarrow$ large $U_t(a)$ (estimated value is uncertain)
 - Large $N(a) \Rightarrow \text{small } U_t(a)$ (estimated value is accurate)
- Select action maximising upper confidence bound (UCB): $a_t = argmax_{a \in A}[Q_t(a) + U_t(a)]$

Optimality of UCB

Hoeffding's Inequality:

Let X_1, \ldots, X_t be i.i.d. random variables in [0,1] with true mean μ , and let \bar{X}_t be the sample mean. Then $\mathbb{P}(\bar{X}_t + u \leq \mu) \leq e^{-2tu^2}$.

$$\mathbb{P}(Q_t(a) + U_t(a) \le Q(a)) \le e^{-2N_t(a)U_t(a)^2}$$

Optimality of UCB

Hoeffding's Inequality:

Let X_1, \ldots, X_t be i.i.d. random variables in [0,1] with true mean μ , and let \bar{X}_t be the sample mean. Then $\mathbb{P}(\bar{X}_t + u \leq \mu) \leq e^{-2tu^2}$.

$$\mathbb{P}(Q_t(a) + U_t(a) \le Q(a)) \le e^{-2N_t(a)U_t(a)^2}$$

If
$$U_t(a) = \sqrt{\frac{-\log p}{2N_t(a)}}$$
 then $e^{-2N_t(a)U_t(a)^2} = p$

Reduce p as we observe more rewards, e.g. $p = \frac{1}{t}$

Optimality of UCB

Hoeffding's Inequality:

Let X_1, \ldots, X_t be i.i.d. random variables in [0,1] with true mean μ , and let \bar{X}_t be the sample mean. Then $\mathbb{P}(\bar{X}_t + u \leq \mu) \leq e^{-2tu^2}$.

$$\mathbb{P}(Q_t(a) + U_t(a) \le Q(a)) \le e^{-2N_t(a)U_t(a)^2}$$

If
$$U_t(a) = \sqrt{\frac{-\log p}{2N_t(a)}}$$
 then $e^{-2N_t(a)U_t(a)^2} = p$

Reduce p as we observe more rewards, e.g. $p = \frac{1}{t}$

$$U_t(a) = \sqrt{\frac{\log t}{2N_t(a)}}$$

UCB

Select action maximising upper confidence bound (UCB):

$$a_t = argmax_{a \in A}[Q_t(a) + c\sqrt{\frac{\log t}{2N_t(a)}}]$$

• Theorem: if $c=\sqrt{2}$ then UCB achieves logarithmic expected total regret

Bayesian Approach

- We could adopt Bayesian interpretation and model distributions over values $\mathcal{R}_a \approx p(r | \theta_a)$ and use model-based approach
- E.g., θ_a could contain the means and variances of Gaussian belief distributions
- Allows us to inject rich prior knowledge θ_a^0
- We can then use posterior belief to guide exploration

Probability Matching

- Probability matching selects action a according to probability that a is the optimal action
- $\pi(a \mid h_t) = \mathbb{P}[Q(a) > Q(a'), a \neq a' \mid h_t], h_t = \{a_1, r_1, \dots, a_{t-1}, r_{t-1}\}$ is history;
- Probability matching is optimistic in the face of uncertainty: Uncertain actions have higher probability of being max
- Can be difficult to compute analytically from posterior

Thompson Sampling

Thompson sampling implements probability matching:

$$\pi(a \mid h_t) = \mathbb{P}[Q(a) > Q(a'), a \neq a' \mid h_t] = \mathbb{E}_{\mathcal{R}|h_t}[\mathbb{I}[a = argmax_{a'}Q(a')]$$

- Use Bayes law to compute posterior distribution $p[\mathcal{R} \mid h_t]$
- Sample a reward distribution ${\mathscr R}$ from posterior
- Compute action-value function $Q(a) = \mathbb{E}[\mathcal{R}_a]$
- Select action maximising value on sample: $a = argmax_{a'}Q(a')$
- Thompson sampling achieves logarithmic lower bound!
